## Abstract

**Background:** Exposure to arsenic via drinking water is a global environmental health problem.

*In utero* exposure to arsenic via drinking water increases the risk of lower respiratory tract infections during infancy and mortality from bronchiectasis in early adulthood.

**Objectives:** We aimed to investigate how arsenic exposure in early life alters lung development and pathways involved in innate immunity.

**Methods:** Pregnant BALB/c, C57BL/6 and C3H/HeARC mice were exposed to 0 (control) or 100µg/L arsenic via drinking water from day 8 of gestation until the birth of their offspring. At two weeks post-natal age mice had somatic growth, lung volume and lung mechanics measured. Fixed lungs were utilised for structural analysis. Lung tissue was collected for gene expression analysis by microarray.

**Results:** The response to arsenic was genetically determined and C57BL/6 mice were the most susceptible strain. Arsenic exposed C57BL/6 mice were smaller in size, had smaller lungs and impaired lung mechanics compared with controls. Exposure to arsenic *in utero* up-regulated the expression of genes in the lung involved in mucous production (*Clca3*, *Muc5b*, *Scgb3a1*), innate immunity (*Reg3γ*, *Tff2*, *Dynlrb2*, *Lplunc1*) and lung morphogenesis (*Sox2*). Arsenic exposure also induced mucous cell metaplasia and increased expression of CLCA3 protein in the large airways.

**Conclusions:** Alterations in somatic growth, lung development and the expression of genes involved in mucociliary clearance and innate immunity in the lung are potential mechanisms through which early life arsenic exposure impacts respiratory health.

## Introduction

Arsenic is a toxic metalloid that contaminates drinking water sources throughout the world, affecting hundreds of millions of people (Mandal and Suzuki 2002). Exposure to arsenic via drinking water in early life has been shown to increase the risk of mortality from bronchiectasis (Smith et al. 2006). Bronchiectasis unrelated to cystic fibrosis (CF) is a chronic, progressive lung disease characterised by cough and sputum production, periodic infectious exacerbations and premature death in adulthood (Grimwood 2011). Bronchiectasis associated with CF is thought to arise from impaired innate immune pathways in the lung (Barker 2002), and while the pathology of non-CF bronchiectasis is poorly understood it is likely that similar mechanisms are involved (Grimwood 2011). The processes linking arsenic exposure in early life and the development of bronchiectasis are unclear.

There is evidence for an effect of *in utero* arsenic exposure on innate immunity. Arsenic exposure during pregnancy induces oxidative stress, increases inflammatory cytokines and reduces T-cell numbers in the placenta, and impairs thymic development in the infant (Ahmed et al. 2011; Raqib et al. 2009). Arsenic exposure during pregnancy has also been shown to increase the risk of lower respiratory tract infections during infancy (Rahman et al. 2011). Recurrent lower respiratory tract infections in early childhood and defective pulmonary immune defences are important risk factors for the development of non-CF bronchiectasis (King et al. 2006). Additionally, *in utero* exposure to arsenic reduces birth weight which is associated with worse respiratory health outcomes in later life (Huyck et al. 2007). Low birth weight infants are more susceptible to lower respiratory tract infections in infancy (McCall and Acheson 1968), have

impaired lung function during childhood (Chan et al. 1989) and are at an increased risk of death from chronic lung diseases in adulthood (Barker et al. 1991). Taken together, these factors suggest that arsenic-induced impairments in growth and development of the lung, along with alterations in immune function may contribute to the development of bronchiectasis in individuals exposed to arsenic *in utero*.

The present study investigates the effects of *in utero* exposure to arsenic on post-natal lung mechanics, lung structure and gene expression using a mouse model. We hypothesised that *in utero* exposure to arsenic via drinking water impairs lung development and immune pathways in the lung.

## Methods

### *Animals and exposure to arsenic*

Animals were sourced from the Animal Resources Centre (Murdoch, Western Australia). Three strains of mice were used; BALB/c, C3H/HeARC (TLR4 intact) and C57BL/6. Animals were treated humanely and with regard for alleviation of suffering. All studies were conducted according to the guidelines of the National Health and Medical Research Council Australia and approved by the institutional Animal Ethics Committee. Pregnant mice were given drinking water containing 0 (control) or 100µg/L of arsenic from gestational day 8 until birth of their offspring (approx. E20) in the form of sodium arsenite (NaAsO<sub>2</sub>). The arsenic concentration of drinking water was confirmed by inductively coupled plasma-mass spectrometry (ICP MS) (Geotechnical Services, Western Australia). After their offspring were born, mothers were all given control drinking water. All mice received the same fixed formulation diet (Specialty Feeds,

Western Australia). The arsenic content in the mouse chow was determined through ion chromatography ICP MS to be  $0.42 \pm 0.02$   $\mu\text{g/g}$  total arsenic and  $0.03 \pm 0.001$   $\mu\text{g/g}$  inorganic arsenic (Centre for Environmental Risk Assessment and Remediation, University of South Australia). Outcomes were measured in the offspring at two weeks of age (BALB/c, n = 29 controls and 24 arsenic exposed; C3H/HeARC, n = 14 controls and 17 arsenic exposed; C57BL/6, n = 24 controls and 32 arsenic exposed).

#### *Thoracic gas volume and lung mechanics*

To measure lung mechanics *in vivo*, mice were anaesthetised, tracheotomised and mechanically ventilated. Plethysmography was used to measure thoracic gas volume (TGV) as described previously (Janosi et al. 2006). Lung mechanics were measured using the forced-oscillation technique as described previously (Sly et al. 2003). Further details are provided in the Supplemental Material, p2.

#### *Stereological analysis of lung structure*

Lung structure was assessed using stereology techniques according to ATS/ERS guidelines (Hsia et al. 2010). Further details are provided in the Supplemental Material, p3.

#### *Gene expression profiling studies*

Peripheral lung tissue was excised from mice and stabilized in RNALater (QIAGEN) (n = 6 litters per treatment group, per strain). The lung tissue was disrupted in TRIzol (Invitrogen) employing a rotor stator homogenizer, and extracted with TRIzol followed by RNeasy (QIAGEN). The quality of the RNA samples was assessed on the bioanalyzer (RIN  $8.30 \pm 0.58$ ). Total RNA

samples were labelled and hybridized to Mouse Gene ST1.0 microarrays (Affymetrix) by the Molecular Genetic Research Services, at the Australian Neuromuscular Research Institute.

The raw microarray data were pre-processed employing the PLIER+16 algorithm (gcbg background subtraction, quantile normalization, iterPLIER summarization) in Expression Console software (Affymetrix) (Bosco et al. 2009). Two low quality microarrays were removed from the analysis. To identify differentially expressed genes, the data were analysed with moderated t-statistics (LIMMA) (Smyth 2004) and plotted as Volcano plots (Supplemental Material, Figure S1). Genes with an absolute moderated t-statistic greater than 3.5 and fold change greater than 2 were considered differentially expressed. The microarray data are available from the Gene Expression Omnibus repository (<http://www.ncbi.nlm.nih.gov/geo/>) (NCBI 2012) under the accession GSE37831. A subset of differentially expressed genes was selected for qRT-PCR validation studies.

#### *Quantitative real-time polymerase chain reaction (qRT-PCR)*

Total RNA was reverse-transcribed with QuantiTect Reverse Transcription Kit (QIAGEN) according to the manufacturer's instructions. Primer assays were purchased from Qiagen and qRT-PCR was performed with QuantiTect SYBR Green (QIAGEN) on the ABI Prism 7900HT (Applied Biosystems). Relative standard curves were prepared from serially diluted RT-PCR products. Data were normalized to the *Eef1a1* gene and multiplied by a scaling factor to obtain whole numbers.

### *Quantification of mucous cells and protein in the airways*

To determine the expression of mucous producing cells and protein expression in the airways, airway histopathology and immunohistochemistry were performed. Following euthanasia the tracheal cannula was instilled with 4% formaldehyde at 10 cmH<sub>2</sub>O. Lungs were embedded in paraffin wax and the left lobe was sectioned for airway histology. Alcian Blue - Periodic Acid Schiff stain was used to detect mucous producing cells, and immunohistochemistry, using an avidin-biotin-peroxidase complex method (Sabo-Attwood et al. 2005), was used to detect CLCA3, MUC5B and REG3 $\gamma$  positive cells (Further details are provided in the Supplemental Material, p.3). The expression of mucous producing and protein positive epithelial cells was calculated as the percentage of positively stained epithelial cells over the total number of epithelial cells in the airway. Airways were classified by their basement membrane perimeter (large >1,500 $\mu$ m, medium > 1,000 $\mu$ m, small <1,000 $\mu$ m).

### *Statistical analysis*

All statistical analyses were conducted using STATA (v9.2; StataCorp, Texas, U.S.A). Group means were compared using t-tests, ANOVA and ANCOVA (where adjustment for a continuous variable was required). Data were transformed as necessary to satisfy the assumptions of normality and homoscedasticity. A p value of less than or equal to 0.05 was considered statistically significant.

## Results

### *Maternal and birth outcomes*

There was no difference in water consumption between mothers given 100µg/L arsenic compared to control mothers for any strain of mouse (BALB/c,  $p = 0.46$ ; C3H/HeARC,  $p = 0.34$ ; C57BL/6,  $p = 0.82$ ) (Supplemental Material, Table S1). There were no differences in litter size (BALB/c,  $p = 0.30$ ; C3H/HeARC,  $p = 0.87$ ; C57BL/6,  $p = 0.54$ ) or gestational age at birth (BALB/c,  $p = 0.84$ ; C3H/HeARC,  $p = 0.21$ ; C57BL/6,  $p = 0.31$ ) between arsenic exposed and control mice. Arsenic exposed C57BL/6 offspring were smaller in birth weight and birth length compared to control C57BL/6 offspring ( $p < 0.001$  and  $p < 0.001$  respectively, Supplemental Material, Table S1). There were no differences in birth weight or length between arsenic exposed and control BALB/c ( $p = 0.15$  and  $p = 0.21$ ) or C3H/HeARC offspring ( $p = 0.18$  and  $p = 0.78$ ). For all analyses reported there was no difference in responses between male and female offspring so data were pooled.

### *Thoracic gas volume and lung mechanics*

Arsenic exposed C57BL/6 mice were significantly smaller in body weight ( $p < 0.001$ ) than controls at two weeks of age and had significantly lower TGV than control offspring ( $p < 0.001$ ), even after adjusting for snout-vent length ( $p = 0.04$ ) (Supplemental Material, Figure S2). Arsenic exposed C57BL/6 mice had significantly higher tissue damping and tissue elastance ( $p < 0.001$  in both cases) compared with C57BL/6 controls (Figure 1). These differences were maintained after adjusting for TGV ( $p = 0.006$  and  $p = 0.004$  respectively). There was no effect of arsenic on airway resistance ( $p = 0.29$ ) in C57BL/6 mice which was maintained after adjusting for TGV ( $p = 0.78$ ).

In C3H/HeARC mice there was no difference in body weight ( $p = 0.38$ ) at two weeks of age for arsenic exposed compared with control mice. TGV was significantly higher in arsenic exposed mice compared with controls ( $p = 0.02$ ) which was maintained after adjusting for snout-vent length ( $p < 0.001$ ) (Supplemental Material, Figure S2). At two weeks of age C3H/HeARC mice exposed to arsenic had significantly higher airway resistance compared with controls ( $p = 0.04$ ) which was still higher after adjusting for TGV ( $p = 0.002$ ). There was no effect of arsenic on tissue damping or tissue elastance ( $p = 0.46$  and  $p = 0.34$  respectively) even after adjusting for TGV ( $p = 0.15$  and  $p = 0.65$ ) (Figure 1).

In BALB/c mice there was no difference in body weight ( $p = 0.31$ ) for arsenic exposed compared with control mice at two weeks of age. TGV was significantly higher in mice exposed to arsenic *in utero* ( $p = 0.05$ ), however, there was no difference after adjusting for snout-vent length ( $p = 0.20$ ) (Supplemental Material, Figure S2). In BALB/c mice there was no difference in airway resistance at 2 weeks of age between the groups ( $p = 0.82$ ) which was also the case after adjusting for TGV ( $p = 0.28$ ). There was evidence to suggest that both tissue damping and tissue elastance were lower in arsenic exposed mice compared with controls ( $p = 0.07$  and  $p = 0.02$  respectively), however, these differences were negated after adjusting for TGV ( $p = 0.65$  and  $p = 0.22$  respectively) (Figure 1).

#### *Stereological analysis of lung structure*

In C57BL/6 mice, lung volume (calculated by stereology) was significantly smaller in arsenic exposed offspring compared with controls ( $p = 0.03$ ). The number of alveoli in the lung ( $p =$

0.01) and the surface area of the lung ( $p = 0.04$ ) were also smaller in arsenic exposed C57BL/6 mice compared with control mice of the same strain, however, there was no difference in the volume of the alveoli ( $p = 0.41$ ) (Figure 2). We found no differences in any of the structural parameters measured between arsenic exposed and control C3H/HeARC or BALB/c mice.

### *Gene expression profiling studies*

Using microarray analysis we identified ten annotated genes in the lung that were differentially expressed as a result of *in utero* exposure to arsenic (Table 1). C57BL/6 mice had seven genes that were differentially expressed, whereas, C3H/HeARC mice had two and BALB/c mice had only one differentially expressed gene(s). Only one gene was down-regulated in response to arsenic, *Olfir1274*, in the C57BL/6 strain. All of the other genes identified as differentially expressed were up-regulated in response to arsenic exposure.

Three out of the ten genes that were up-regulated (*Clca3*, *Muc5b* and *Scgb3a1*) are involved in the regulation and/or secretion of mucous in the airways (Roy et al. 2011). These genes were all up-regulated in C57BL/6 mice. Four out of the ten genes (*Lplunc1*, *Tff2*, *Reg3 $\gamma$*  and *Dynlrb2*) that were up-regulated are involved in innate immune function (Bingle and Craven 2002; Jin et al. 2009; McAleer et al. 2011; Nikolaidis et al. 2003). *Lplunc1*, *Tff2* and *Reg3 $\gamma$*  were up-regulated in C57BL/6 mice and *Dynlrb2* was up-regulated in C3H/HeARC mice. We also identified a gene involved in lung branching morphogenesis and epithelial cell differentiation, *Sox2* (Gontan et al. 2008), which was up-regulated in C3H/HeARC mice. In BALB/c mice, an oncogene (*Ssxb10*) was the only gene up-regulated (Chen et al. 2003).

### *Validation of array expression using qRT-PCR*

Using qRT-PCR, we validated the expression of 4 genes in C57BL/6 mice (*Clca3*, *Muc5b*, *Tff2*, *Reg3g*) and 1 gene in C3H/HeARC mice (*Sox2*). In all cases, the expression patterns, normalized to the *Eef1a1* gene, correlated to those obtained in the microarray analysis (Figure 3).

### *Quantification of mucous and protein in the airways*

We used Alcian blue/Periodic Acid Schiff staining and immunohistochemistry to quantify mucous producing cells, CLCA3, MUC5B and REG3 $\gamma$  protein in the airways of BALB/c, C3H/HeARC and C57BL/6 mice (Figure 4). We found that arsenic exposure *in utero* caused mucous cell metaplasia in the large ( $p < 0.001$ ) and medium ( $p = 0.02$ ) airways of C57BL/6 mice and increased the expression of CLCA3 ( $p < 0.01$ ) and REG3 $\gamma$  ( $p = 0.02$ ) protein in the large airways of C57BL/6 mice (Figure 5). The levels of MUC5B protein were low and not differentially expressed between the airways of arsenic exposed and control C57BL/6 mice. There were no differences in the number of mucous producing cells, CLCA3, MUC5B or REG3 $\gamma$  proteins between the airways of arsenic and control mice of either the BALB/c or C3H/HeARC strains (data not shown).

## **Discussion**

Exposure to arsenic *in utero* has been shown to increase morbidity from lower respiratory tract infections in infancy and increase mortality from bronchiectasis in adulthood (Rahman et al. 2011; Smith et al. 2006). In this study, we have shown that the response to arsenic in mice is genetically determined and the C57BL/6 strain was the most susceptible of the three strains

studied. *In utero* exposure to arsenic impaired somatic growth, lung volume and parenchymal lung mechanics in C57BL/6 mice. Additionally, we have shown that exposure to arsenic during gestation was capable of altering the expression of genes which function in mucociliary clearance, innate immunity and lung growth in the offspring. Arsenic also induced mucous cell metaplasia and increased expression of CLCA3 protein in the airways of C57BL/6 mice. Increased mucous secretion and altered lung growth may impair the ability of the airways to clear pathogens and thus provides a potential mechanism by which exposure to arsenic increases the risk of developing chronic localised infections leading to bronchiectasis.

Exposure to arsenic *in utero* impaired intrauterine growth and lung development. Arsenic exposed C57BL/6 mice were small for gestational age, had lower lung volume, lung surface area and alveolar number and impaired lung mechanics compared with control mice of the same strain. This finding supports results from a recent study which also found that C57BL/6 mice exposed to arsenic *in utero* had deficits in growth in early life (Kozul-Horvath et al. 2012). Impairments to body size and lung size during infancy may result in airways and alveoli that are prone to closure and collapse thus increasing the susceptibility to obstruction and increased pathogen load. Low birth weight is associated with impaired lung function and increased mortality from obstructive lung disease (Barker et al. 1991; Hulskamp et al. 2009). A potential mechanism for the observed intrauterine growth restriction may be oxidative stress caused by arsenic induced production of reactive oxygen species inducing placental insufficiency (Vahter 2007). This is supported by the knowledge that the mouse strain most sensitive to arsenic, C57BL/6 mice, are highly susceptible to the oxidative stress effects of cigarette smoke and bleomycin compared to other strains (Chen et al. 2001a; Yao et al. 2008). There is evidence from

cigarette smoke exposure models that intrauterine growth restriction alone can cause alterations in early life lung function (Larcombe et al. 2011). It is therefore possible that the effects of arsenic exposure on body weight, lung function and lung size in this study, in the C57BL/6 mice at least, were due to arsenic altering the nutritional status of the offspring. However, we also identified responses, such as alterations in lung gene expression and airway morphology that seem to be unique to arsenic exposure and have yet to be linked with altered nutritional status. It is clear that exposure to arsenic during pregnancy is having a significant effect on intrauterine growth which may predispose infants to chronic lung diseases through impairments in lung growth and development.

We found that arsenic exposure during pregnancy was capable of altering the expression of genes in the lung at two weeks of age. The differentially expressed genes identified are involved in mucous production, innate immunity and lung morphogenesis pathways. The gene that was most highly up-regulated was the calcium-activated chloride channel, *Clca3* gene. This gene has been detected in goblet cells within the tracheal and bronchial epithelium of mice when metaplasia of mucous cells is present (Leverkoehne and Gruber 2002) and is thought to play a role in the mucous hyper-secretion seen in chronic obstructive pulmonary disease (COPD) and CF in humans (Rogers 2003; Shale and Ionescu 2004). Blocking the production and/or activity of *Clca3* can inhibit the production of mucous, whereas up-regulation can enhance mucous production (Zhou et al. 2002). *Clca3* has been implicated in the regulation of mucous secretion by controlling the packaging and/or release of secreted mucins such as MUC5AC and MUC5B, which are the major gel-forming mucins in respiratory secretions. (Nakanishi et al. 2001; Zhou et al. 2002). MUC5B levels are increased in sputum from COPD and CF patients compared to

sputum from healthy airways (Kirkham et al. 2002), and are associated with the overproduction of mucous in diseased airways (Chen et al. 2001b). In our study *Muc5b* gene expression was also up-regulated and mucous cell metaplasia was present in the airways of C57BL/6 mice. Mucous cell metaplasia is a pathological feature of various respiratory diseases including both CF and non-CF bronchiectasis, COPD and asthma (Kim 1997). Mucous hyper-secretion can hinder the ability of the cilia to clear mucous from the airways, thus increasing the susceptibility to viral and bacterial colonisation and infection (Shale and Ionescu 2004). Increased mucous in the airways may also lead to obstruction and contribute to abnormalities in lung mechanics (Rose et al. 2001). Increased mucous production resulting in increased susceptibility to respiratory infections combined with airway obstruction can lead to chronic localized inflammation: a hallmark of the bronchiectatic lung (Barker 2002).

As well as increasing the risk of infection, arsenic exposure *in utero* may compromise the immune response to respiratory infections. In this study we identified four genes that play a role in modulating the immune system that were up-regulated by exposure to arsenic. Trefoil factor 2 (*Tff2*) protein has a role in mucosal epithelial restitution and wound healing in the gastrointestinal tract (Podolsky 2000). In the lung, TFF2 protein expression is increased in mucous cells of allergen challenged mice and is up-regulated in airway epithelial cells in subjects with asthma (Kuperman et al. 2005; Nikolaidis et al. 2006). *Tff2* has also been identified as a candidate gene associated with strain-dependent differences in lung function in mice (Ganguly et al. 2007). REG3 $\gamma$  is a protein with antimicrobial activity identified to play a role in innate mucosal immunity in the gastrointestinal tract (Zheng et al. 2008) and more recently in the lung (McAleer et al. 2011). *Dynlrb2* is differentially expressed in patients with primary ciliary

dyskinesia, a condition that can lead to the development of bronchiectasis due to impairment of mucociliary clearance (Geremek et al. 2011). *Dynlrb2* has also been shown to regulate the TGF- $\beta$  signalling pathway (Jin et al. 2009). Increased production and activation of TGF- $\beta$  has been linked to immune defects associated with the susceptibility to opportunistic infection (Letterio and Roberts 1998). LPLUNC1 is a protein suggested to play a role in innate immunity in the lung, mouth and nose, through either direct antibacterial actions or by indirect neutralizing activity (Bingle and Craven 2002). Mucous metaplasia and altered immune pathways in the lung may partially explain the increased susceptibility to and exacerbated response to influenza infection seen in a mouse model of arsenic exposure (Kozul et al. 2009). Importantly, compromised innate immune pathways in the lung during infancy may increase the risk of respiratory infections in early life, when susceptibility to infection is high, and increase the risk of developing chronic lung disease in adulthood.

In order to give these observations context it is important to recognize that there were some limitations to the present study. There was a small amount (0.03  $\mu\text{g/g}$ ) of inorganic arsenic in the mouse chow given to all the mice in our study, which has the potential to alter gene expression in the liver and lung (Kozul et al. 2008). However, the concentrations of inorganic arsenic in our study were low, the same diet was given to all of the mice and we still detected differences in a variety of outcomes, including gene expression, as a result of the exposure to 100 $\mu\text{g/L}$  arsenic in drinking water. Another limitation of the study is that only a single concentration of arsenic (100 $\mu\text{g/L}$ ) was used in this study. This represents a relatively high concentration of arsenic (ten times higher than the current World Health Organisation maximum contaminant level) and the effects observed in this study may not reflect changes at higher or lower doses. In the present

study we only identified a small number of differentially expressed genes as a result of arsenic exposure. Even by relaxing our criteria for differential expression we were not able to identify any functionally coherent pathways using more complex methods of analysis. As we assessed the lung tissue sometime after the arsenic exposure had ceased it is possible that we missed some pathways and there is value in examining expression networks in lung tissue during exposure in the future (Petrick et al. 2009). Our study, however, has identified and validated a number of genes that we believe provide important clues to the underlying mechanisms and given their function are likely to be important in the lung disease phenotype induced by arsenic exposure in humans (e.g. infection/bronchiectasis). We only examined the effects of arsenic exposure on the lung in offspring at two weeks of age in the present study. The long term effects of arsenic exposure on lung development may differ between strains whereby changes in parenchymal growth may manifest at different ages (Ngalame et al. 2012). An analysis of later time points may provide further information about the genetic basis of susceptibility to arsenic induced lung disease.

In this study we have shown that *in utero* exposure to arsenic via drinking water impairs lung development, resulting in reduced lung size, and impaired lung structure and function. The response to arsenic was genetically determined and the C57BL/6 strain was the most susceptible. Arsenic exposure *in utero* altered the expression of genes that regulate innate immunity, mucous production and morphogenesis of the lung. Arsenic-induced alterations in the development of lung structure and innate immunity may reduce the ability to clear respiratory pathogens, during a period of high susceptibility in infancy (Simoes 1999). As respiratory infections are one of the leading causes of mortality in children under five in developing countries (World Health

Organization 2011), arsenic induced increases in susceptibility to infection can have devastating effects on infant morbidity and mortality in affected areas. Additionally, recurrent respiratory infections throughout life can contribute to the development of chronic lung diseases, such as bronchiectasis, in adulthood. The evidence from our mouse model is that *in utero* exposure to arsenic impairs lung development resulting in altered structure, function and gene expression in infancy. Further investigation into how arsenic affects lung development in humans will be essential to understand and prevent escalating morbidity and mortality from respiratory disease in arsenic exposed populations.

**Table 1** Genes altered by arsenic exposure

Gene symbols	Gene name	Function	Fold change
<b>C57BL/6</b>			
<i>Clca3</i>	Chloride channel calcium activated 3	Regulation of mucous production and secretion (Zhou et al. 2002)	15.05
<i>Lplunc1</i>	Long palate, lung and nasal epithelium carcinoma-associated protein 1	Innate immunity in mouth, nose and lungs (Bingle and Craven 2002)	13.72
<i>Reg3γ</i>	Regenerating islet-derived 3 gamma	Innate immunity – antibacterial properties in the mucous secretions (McAleer et al. 2011)	8.77
<i>Scgb3a1</i>	Secretoglobulin, family 3A, member 1	Secretory cell subtype in the lung (Roy et al. 2011)	5.80
<i>Tff2</i>	Trefoil factor 2 (spasmolytic protein 1)	Innate immunity- allergen induced gene, expressed in mucous cells (Nikolaidis et al. 2003)	3.26
<i>Muc5b</i>	Mucin 5, subtype B, tracheobronchial	Major mucin in respiratory mucous (Kirkham et al. 2002)	3.16
<i>Olfr1274</i>	Olfactory receptor 1274	Olfaction	-2.07
<b>C3H/HeARC</b>			
<i>Dynlrb2</i>	Dynein light chain roadblock-type 2	Regulation of TGF-B pathway (Jin et al. 2009)	2.36
<i>Sox2</i>	SRY-box containing gene 2	Lung branching morphogenesis and epithelial cell differentiation (Gontan et al. 2008)	2.27
<b>BALB/c</b>			
<i>Ssxb10</i>	Synovial sarcoma, X member B, breakpoint 10	Cancer (Chen et al. 2003)	2.41

## Figure Legends

**Figure 1.** Airway resistance ( $R_{aw}$ ), tissue damping (G) and tissue elastance (H) plotted against thoracic gas volume (TGV) for two week old BALB/c (A, B, C), C3H/HeARC (D, E, F) and C57BL/6 (G, H, I) mice exposed to 100  $\mu\text{g/L}$  arsenic (closed circles) via drinking water or control water (open circles) from d8 gestation to birth (\* indicates significantly different to control,  $p < 0.05$ ).

**Figure 2.** Lung volume ( $V_L$ ), number of alveoli in the lung ( $N(a,L)$ ), alveolar surface area ( $S_v(a)$ ), and alveolar volume ( $V_a$ ) for two week old BALB/c, C3H/HeARC and C57BL/6 mice exposed to 100  $\mu\text{g/L}$  arsenic (lined bars) via drinking water or control water (open bars) from d8 gestation to birth (\* indicates significantly different to control,  $p < 0.05$ ).

**Figure 3.** Validation of microarray gene expression by QRT-PCR. A subset of genes, *Muc5b*, *Clca3*, *Tff2*, *Reg3 $\gamma$* , and *Sox2*, had microarray expression validated using QRT-PCR. All values were normalized to the *Eef1a1* gene (\* indicates significantly different to control,  $p < 0.05$ ).

**Figure 4.** Airway histology showing that arsenic induces mucous cell metaplasia and increases CLCA3 protein expression in the airways of C57BL/6 mice. Lung sections stained with Alcian Blue/Periodic Acid Schiff (top) and an antibody to CLCA3 (bottom) show increased mucus cell (dark purple stain) and CLCA3 protein (brown stain) expression in the airways of C57BL/6 mice exposed 100  $\mu\text{g/L}$  arsenic (B, D) via drinking water or control water (A, C) from d8 gestation to birth. Scale bars 200 $\mu\text{m}$ .

**Figure 5.** Quantitation of mucous producing cells, and CLCA3, MUC5B and REG3 $\gamma$  positive epithelial cells in the airways of C57BL/6 mice. Values are expressed as the percentage of mucous producing

epithelial cells and protein positive epithelial cells over the total number of epithelial cells in large, medium and small airways of C57BL/6 mice exposed to 100 µg/L arsenic (closed bars) via drinking water or control water (open bars) from d8 gestation to birth (\* indicates significantly different to control,  $p < 0.05$ ).
